
Simple: This chart uses existing drift data only. No new drift run was made. The band shows the range of the proposed detection levels for Australian coasts. The northern tail is made from few flight paths, so its shape is not reliable.
Technical: Mean of two ocean models (GLORYS12+ERA5, GlobCurrent+ERA5), 50 km recovery bandwidth, window 8 Mar 2014–30 Jun 2016. Finds term from run A node surfaces (rebuilt); Australian term from the 178-node 15–160 E pilot, reconstructed with the module's saturating law Delta = -k ln(1+W/cF) (fitted per model to options B and C) and spread by inverse-distance weighting. Detection levels relative to find coasts, anchor: find coasts at peak awareness = 0.65; Major Cities 1.0, Inner Regional 0.77, Outer Regional 0.31, Remote 0.077, Very Remote 0; band = merged classes at their lower and upper values. Points on the median impact longitude per latitude (run J D0, q=1/3, C2 silent) and 50 NM either side. Pilot-node Monte Carlo noise about 1.3–1.5 log-likelihood units per node; run J northern mass rests on few lineages (pooled L_eff about 120 north of 33 S). Post hoc sensitivity, not a headline result.
